**Abstract.** The pre-eminent role played by software composition, and more particularly service composition, in modern software development, together with the complexity of workflow languages such as WS-BPEL have made composite service testing a topical issue. In this article we contribute to this issue with an automatic testing approach for WS-BPEL orchestrations. Compared to related work, we support WS-BPEL data computations and exchanges, while overcoming the consequential state explosion problem. This is achieved through the use of symbolic transition system models and their symbolic execution. Throughout the article, we illustrate our approach on a realistic medium-size example.

**keywords:** service composition, orchestration, formal testing, test-case generation, WS-BPEL, transition systems, symbolic execution.

## 1 Introduction

Service composition, and more specifically orchestration, has emerged as a cornerstone to develop added-value distributed applications out of reusable and loosely coupled software pieces. The WS-BPEL language [1], or BPEL for short, has become the de-facto standard for Web service orchestration and is gaining industry-wide acceptance and usage. This makes BPEL orchestration correctness a topical issue, all the more because of BPEL complexity. This has been partly addressed by automatic service composition or adaptation processes [2, 3]. Still, these usually assume that services convey semantic annotations, which is, currently, seldom the case. Service orchestrations are therefore developed in a more usual way, *i.e.*, from specifications which are thereafter implemented by service architects. Numerous model-based verification approaches have been proposed for BPEL, *e.g.*, translating BPEL to automata, Petri nets or process algebras [4]. These approaches are especially valuable to check if an orchestration specification is correct. Still, as far as the correctness of an implementation wrt. a specification is concerned, these approaches fall short as, *e.g.*, one may expect service providers to publicise (Abstract) BPEL descriptions of *what* their

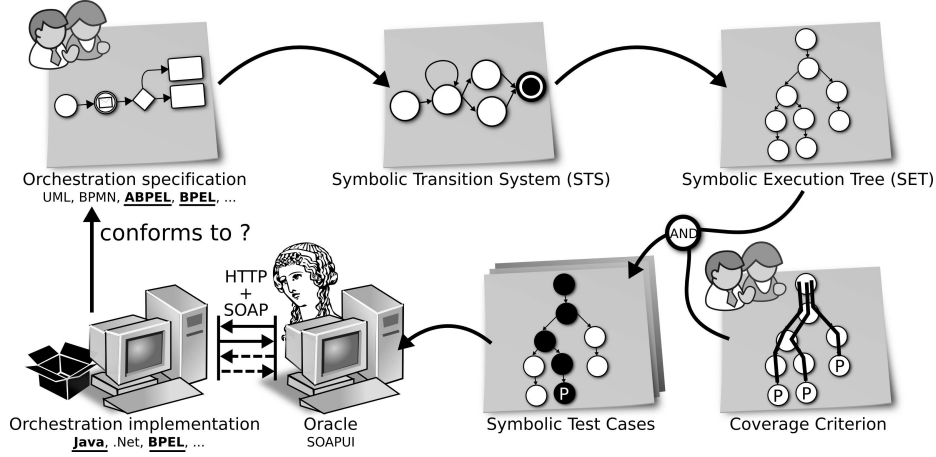

Fig. 1. Overview of the proposed framework

services do, but not *how* they do it. Here, testing comes as a solution to ensure (i) that some sub-service used in an orchestration really conforms to its publicised behavioural interface, and (ii) that the service orchestration itself conforms to the behavioural interface to be publicised after its deployment.

In this paper, we propose a formal framework for the testing of service orchestrations (Fig. 1). The orchestration specification is first translated into a formal model, namely a Symbolic Transition System (STS) [5]. In a second step, a Symbolic Execution Tree (SET) is computed from this STS. It supports the retrieval of the STS execution semantics, while avoiding the usual state-explosion problem in presence of unbounded data types, as used in full-fledged BPEL. Given a coverage criterion, we generate from the SET a set of execution paths which are finally run by a test oracle against the orchestration implementation.

With reference to related work, our contributions are manifold. A first contribution is the support for the rich XML-based data types available in BPEL. This is achieved first by relying on a symbolic model rather than on the labelled transition systems (LTS) that are usually used –either directly or indirectly from process algebraic or Petri net descriptions– as BPEL models. LTS are known to cause over-approximation or unimplementable test cases (when data are simply abstracted away), and state explosion problems (when message parameters or variables are flattened wrt. their infinite domains). Both are avoided using STS. Symbolic execution [6] also takes part in avoiding state explosion by representing message parameters and variables using symbolic values instead of concrete data. A second contribution is the possibility to take different orchestration specification languages (UML, BPMN, (A)BPEL) into account. This is achieved thanks to the STS model which has already proven to be valuable, *e.g.*, for UML [7], and is here used for BPEL.

Finally, we propose a comprehensive language-to-language model-based testing framework, while most model-based (verification or testing) approaches targeted at orchestration languages either ignore the retrieval of the formal model from the orchestration specification, ignore or over-simplify the rich XML-based data types of services, or do not tackle the execution of test cases against a running service implementation. As a consequence, we have applied our framework to two realistic medium-size case studies, including our extended version, presented herein, of the loan approval service [1].

The remaining of the paper is organised as follows. The following Section introduces our case study. The orchestration and STS models are presented in Section 3. The principles of symbolic execution and the computation of a finite SET from an STS are described in Section 4. Section 5 addresses the retrieval of symbolic test cases from a SET, our online testing algorithm, and tool support. Finally Section 6 discusses related work and we end in Section 7 with conclusions and perspectives.

## 2 Running Example

In this Section we introduce our **xLoan** case study. It is an extension of the well-known loan approval example presented in the BPEL standard [1], which usually serves for demonstration purposes in articles on BPEL verification. Our extensions are targeted at demonstrating our support for BPEL important features: complex data types, complex service conversations including message correlation, loops and alarms. Hence, more complex and realistic data types are used, to model user information, loan requests and loan proposals. The specified sub-services respectively deal with loan approval (**BankService**) and black listing (**BlackListingService**), with users not being blacklisted asking for low loans ( $\leq 10,000$ ) getting loan proposals without requiring further approval. As-is, these services resemble the ones proposed in [1]. Yet, once a loan is accepted, proposals may be sent to the requester. Further communication then takes place, letting the requester select one proposal or cancel, which is then transmitted to **BankService**. If the selected offer code is not correct the requester is issued an error message and may try again (select or cancel). Timeouts are also modelled, and the bank is informed about cancelling if the requester does not reply in a given amount of time (2 hours).

There is no official graphical notation neither for orchestration architectures (WSDL interfaces and partner links), nor for the imported data types (XML Schema files) or the service conversation (BPEL `<process>` definition). For the former ones (Fig. 2) we use the UML notation that we extend with specific stereotypes in order to represent message types, correlations and properties (see Sect. 3 for their semantics). Moreover, XML namespaces are represented with packages. Additionally, there is currently an important research effort on relating the Business Process Modelling Notation (BPMN) with Abstract BPEL or BPEL code [8]. Therefore, concerning the graphical presentation of service conversations, we take inspiration from BPMN, while adding our own annotations

Fig. 2. xLoan Example – Data and Service Architecture

supporting relation with BPEL. Communication activities are represented with the concerned partnerlink (USER for the user of the orchestration, BK or BL for the two sub-services), operation, input/output variables, and, when it applies, information about message correlation.

Figure 3 presents the orchestration specification. The overall process is presented in Figure 3, upper part, while its lower part concerns the (potentially looping) subprocess, GL&S (*Get Loan and Select*), for loan proposal selection.

### 3 From BPEL to STS

In this Section we present our formal models for services and orchestrations. We also discuss model retrieval from BPEL.

Services may expose information at different interface description levels. The basic level is the *signature level* where a service describes the set of operations it provides. Complex services, including state-full ones, additionally provide a *behavioural description* (conversation) of the way its operations should be called. In this work we focus on these two levels, which are the ones widely accepted and used, with respectively the WSDL and (A)BPEL languages.

**Signatures.** The *signature* of a service is described using a combination of XML schema (exchanged data structures) and WSDL (operations and messages). We model it as a tuple  $\Sigma = (\mathcal{D}, \mathcal{O}, \mathcal{P}, in, out, err, \pi, \downarrow)$ .

$\mathcal{D}$  is a set of domains.  $dom(x)$  denotes the domain of  $x$ .  $\mathcal{O}$  is a set of (provided) operations. Operations may be either one-way or two-way.  $in, out, err : \mathcal{O} \rightarrow \mathcal{D} \cup \{\perp\}$  denote respectively the input, output, or fault message of an operation ( $\perp$  when undefined, e.g.,  $out(o) = err(o) = \perp$  for any one-way operation  $o$ ).

**Partnership.** An orchestration is built around a partnership, *i.e.*, a set of partner signatures, corresponding to required operations, and a set of signatures for the orchestration itself, corresponding to provided operations. In the sequel we

suppose, without loss of generality, that an orchestration has only one of these, named **USER**. A *partnership*  $\rho$  is an  $ID$ -indexed set of signatures  $\{\Sigma_i\}_{i \in ID}$ , where  $ID$  is a set of names ( $\text{USER} \in ID$ ). Two domains with the same name, including the namespace part, in two signatures correspond to the same thing. More specifically, we suppose they have the same formal semantics.

**Events.** The semantics of a service conversation depends on message-based communication, which is modelled using *events*. An input event,  $pl.o?x$ , with  $o \in \mathcal{O}(\Sigma_{pl})$  and message variable  $x$  such that  $dom(x) = in(o)$ , corresponds to the reception of the input message of operation  $o$  from partner link  $pl$ . Accordingly, we define output events  $pl.o!x$  ( $dom(x) = out(o)$ ). Service calls may also yield errors (message faults). This is modelled with fault output events,  $pl.o!!x$ , and fault input events,  $pl.o??x$  ( $dom(x) = err(o)$ ). We omit BPEL port types here for simplicity reasons (full event prefixes would be, *e.g.*,  $pl.pt.o?x$  for the first example above with input on port type  $pt$ ).  $Ev^?$  (resp.  $Ev^!$ ,  $Ev^{??}$ , and  $Ev^{!!}$ ) is the set of input events (resp. output events, fault input events, and fault output events).  $Ex$  is the set of internal fault events, that correspond to faults possibly raised internally (not in messages) by the orchestration process. We also introduce specific events:  $\tau$  denotes non-observable internal computations or conditions,  $\chi$  denotes time passing (time constraints in services are generally soft, hence discrete time is a valid abstraction), and  $\surd$  denotes the termination of a conversation (end of a session). We define  $Ev = Ev^? \cup Ev^! \cup Ev^{??} \cup Ev^{!!} \cup Ex \cup \{\tau, \chi, \surd\}$ . We also define  $hd$  as  $\forall * \in \{?, ??, !, !!\}, hd(pl.o * x) = pl.o$ , and  $hd(e) = e$  for any other  $e$  in  $Ev$ .

**Orchestration.** Different models have been proposed to support behavioural service discovery, verification, testing, composition or adaptation [4, 9–11]. They mainly differ in their formal grounding (Petri nets, transition systems, or process algebra), and the subset of service languages being supported. We base on [12] due to its good coverage of the main BPEL language constructs. Moreover, its process algebraic style for transformation rules enables a concise yet precise and operational model, which is, through extension, amenable to symbolic execution. In this objective, we extend the formalising given in [12] to support a wider subset of BPEL (see below discussion on *BPEL to STS transformation*), including data in computation and messages. As a consequence, our behavioural model grounds on (discrete timed) Symbolic Transition Systems (STS) in place of the discrete timed Labelled Transition Systems (dtLTS) presented in [12].

A *Symbolic Transition System* (STS), is a tuple  $(\mathcal{D}, \mathcal{V}, S, s_0, T)$  where  $\mathcal{D}$  is a set of domains (as in signatures),  $\mathcal{V}$  is a set of variables with domain in  $\mathcal{D}$ ,  $S$  is a non empty set of states,  $s_0 \in S$  is the initial state, and  $T$  is a (potentially non-deterministic) transition relation,  $T \subseteq S \times \mathcal{T}_{\mathcal{D}^{Bool}, \mathcal{V}} \times Ev \times 2^{Act} \times S$ , with  $\mathcal{T}_{\mathcal{D}^{Bool}, \mathcal{V}}$  denoting boolean terms,  $Ev$  a set of events and  $Act$  a set of actions (of the form  $v := t$  where  $v \in \mathcal{V}$  is a variable and  $t \in \mathcal{T}_{\mathcal{D}, \mathcal{V}}$  a term). The transition system is called symbolic as the guards, events, and actions may contain variables. An element  $(s, g, e, A, s')$  of  $T$  is denoted  $s \xrightarrow{[g] \ e \ / \ A} s'$ . When there is no guard (*i.e.*, it is true) it is omitted. The same yields for the actions. We impose that variables used in the STS transitions are defined in  $\mathcal{V}$ . STS have been introduced

under different forms (and names) in the literature [5], to associate a behaviour with a specification of data types that is used to evaluate guards, actions and sent values. This role is played here by  $\mathcal{D}$  which is a superset of all partners' domains. Consistency of the union is ensured by the above-mentioned restriction on domains sharing names.

An *orchestration*  $\mathcal{Orch}$  is a tuple  $(\rho, \mathcal{B}, \mathcal{C})$  where  $\rho$  is a partnership,  $\mathcal{B}$  is an STS, and  $\mathcal{C}$  is a set of correlation sets, *i.e.*, a name and a set of associated properties, denoted with *props*. Sometimes a single property is used (*e.g.*, an identifier), but more generally this is a set (*e.g.*, name and surname). A correlation value is a value of a structured domain with items corresponding to the properties. We impose that  $\mathcal{B}$  is correct wrt.  $\rho$ , *i.e.*, its set of events correspond to partner links and operations defined in  $\rho$ , which can be syntactically checked.

**BPEL to STS transformation.** BPEL is first abstracted away from its concrete syntax using process constructors. The transformation rules are then presented in a process algebraic structural operational semantics way, using one or several rules for each constructor. Due to lack of room, the presentation of the transformation rules is provided in [13]. With reference to the variables used in the BPEL specification, anonymous variables ( $va_i$ ) are added in  $\mathcal{V}(\mathcal{B})$  to follow BPEL communication semantics. Moreover, for each correlation set  $c$  in  $\mathcal{C}$ , we also add two variables,  $vcs_c$  (to denote the value of  $c$ ) and  $vcs_{cinit}$  (to check whether  $c$  is initialised or not).

We support the main BPEL activities. With reference to [12], we support data (in computation, conditions and message exchange), message correlation, message faults, parallel processing (flows) and the `until` activity. The catch construct of synchronous `invoke` is not directly supported but it can be simulated using a fault handler in a scope around the `invoke`. Links, the `foreach` activity, fault variables in fault handlers, compensations handlers, and termination handlers are future work.

**Application.** The STS obtained from the example presented in Section 2 is presented in Figure 4 where `tau` (resp. `tick`, `term`) denote  $\tau$  (resp.  $\chi$ ,  $\sqrt{\phantom{x}}$ ). The zoom corresponds to the `while` part. One may notice states 16 (`while` condition test), 17/33 (`pick`), 34 (`onAlarm` timeout), and 18/23 (`correlation` testing).

## 4 Symbolic Execution

Symbolic execution [6] (SE) is a program analysis technique that has been originally proposed to overcome the state explosion problem when verifying programs with variables. SE represents values of the variables using symbolic values instead of concrete data [14]. Consequently, SE is able to deal with constraints over symbolic values, and output values are expressed as a function over the symbolic input values. More recently these techniques have been applied to the verification of interacting/reactive systems, including testing [14–16].

**SE-Trees.** The SE of a program is represented by a *symbolic execution tree* (SET), where nodes,  $\mathcal{N}_{\text{SET}}$ , are tuples  $\eta_i = (s, \pi, \sigma)$  made up of the program counter,  $s$ , the symbolic values of program variables,  $\sigma$ , and a path condition,

Fig. 4. xLoan Example – Symbolic Transition System

$\pi$ . Let  $\mathcal{V}_{\text{symb}}$  be a set of (symbolic) variables (representing symbolic values), disjoint from the program variables,  $\mathcal{V}$  ( $\mathcal{V} \cap \mathcal{V}_{\text{symb}} = \emptyset$ ).  $\sigma$  is a map  $\mathcal{V} \rightarrow \mathcal{V}_{\text{symb}}$ . The path condition (PC) is a boolean formula with variables in  $\mathcal{V}_{\text{symb}}$ . The PC accumulates constraints that the symbolic variables must fulfil in order to follow a given path in the program.

Since we apply SE to the STS obtained from orchestrations, the program counter is an STS state, and  $\mathcal{V}$  corresponds to the STS variables (either simple, message type, anonymous, or correlation variables from BPEL). The edges of the SET,  $\mathcal{E}_{\text{SET}}$ , are elements of  $\mathcal{N}_{\text{SET}} \times Ev_{\text{symb}} \times \mathcal{N}_{\text{SET}}$  (may be non deterministic), where  $Ev_{\text{symb}}$  corresponds to the STS events ( $Ev$ ) with symbolic variables in place of variables.

**SET edge computation.** The SET is computed in a BFS fashion as follows. The root is  $(s_0, true, \sigma_0)$  where  $s_0$  is the STS initial state and  $\sigma_0$  is the mapping of a fresh variable for each variable of the STS. Each transition  $s \xrightarrow{[g] \ e \ / \ A} s'$  then corresponds to an edge  $(s, \pi, \sigma) \xrightarrow{e'} (s', \pi', \sigma')$ , computed as follows:

1. **guard:**  $\pi^G = \pi \wedge g[\sigma(v_i)/v_i]_{v_i \in \text{vars}(g)}$  ( $\pi^G = \pi$  if there is no guard)
2. **event:**  $e', \sigma^E = \begin{cases} pl.o * v_s, & \sigma[v \rightarrow v_s] \text{ if } e = pl.o * v, * \in \{?, ??\} \\ pl.o * \sigma(v), \sigma & \text{if } e = pl.o * v, * \in \{!, !!\} \\ e, & \sigma \text{ otherwise} \end{cases}$

with  $v_s = \text{new}^1(\mathcal{V}_{\text{symb}}, \sigma)$ . If  $e$  is a sub-service invocation return ( $e = pl.o *$

- $v_{out}, * \in \{?, ??\} \wedge pl \neq \text{USER}$ ), we set  $\pi^E = \pi(o)[\sigma^E(v_{in})/in, v_s/out]$ , where  $e = pl.o!v_{in}$  is the label of the (unique) transition before the one we are dealing with, to take into account the operation specification. Else,  $\pi^E = \pi^G$ .
3. **actions** ( $A = \{x_i/path_i := t_i\}_{i \in \{1, \dots, n\}}$ ):  
 $\pi_i^A = \pi_{i-1}^A \wedge (v_{s_{x_i}}/path_i = t_i[\sigma^E(v_j)/v_j]_{v_j \in vars(t_i)})$   
 with  $\Delta = \{x \in \mathcal{V} \mid (x/path_i := t_i) \in A\}$ ,  $\{v_{s_x}\}_{x \in \Delta} = new^\# \Delta(\mathcal{V}_{\text{symp}}, \sigma^E)$ ,  
 $\sigma' = \sigma^E\{[v_{s_x}/x]\}_{x \in \Delta}$ ,  $\pi_0^A = \pi^E$ , and  $\pi' = \pi_n^A$ .

where  $vars$  denotes the variables in a term,  $new^n(\mathcal{V}_{\text{symp}}, \sigma)$  denotes the creation of  $n$  new (fresh) symbolic variables wrt.  $\sigma$ ,  $t[y/x]$  denotes the substitution of  $x$  by  $y$  in  $t$ , and  $\sigma[x \rightarrow x_s]$  denotes  $\sigma$  where the mapping for  $x$  is overloaded by the one from  $x$  to  $x_s$ .  $\Delta$  is the set of variables that are modified by the assignments. For each of these, we have a new symbolic variable. We denote by  $may(\eta)$ ,  $\eta \in \mathcal{N}_{\text{SET}}$ , the set  $\{e \mid \exists(\eta, e, \eta') \in \mathcal{E}_{\text{SET}}\}$ .

**Feasible paths.** Edges with inconsistent path conditions may be cut off while computing the SET. For this, we check when computing a new node  $\eta$  if  $\pi(\eta)$  is satisfiable (there exists a valuation of variables in  $\pi$  such that  $\pi$  is true, if not, we cut the edge off). This is known to be an undecidable problem in general. Therefore, if the constraint solver does not yield a solution (or a contradiction) in a given amount of time, we cut the edge off and we issue a warning specifying that the test process is to be incomplete.

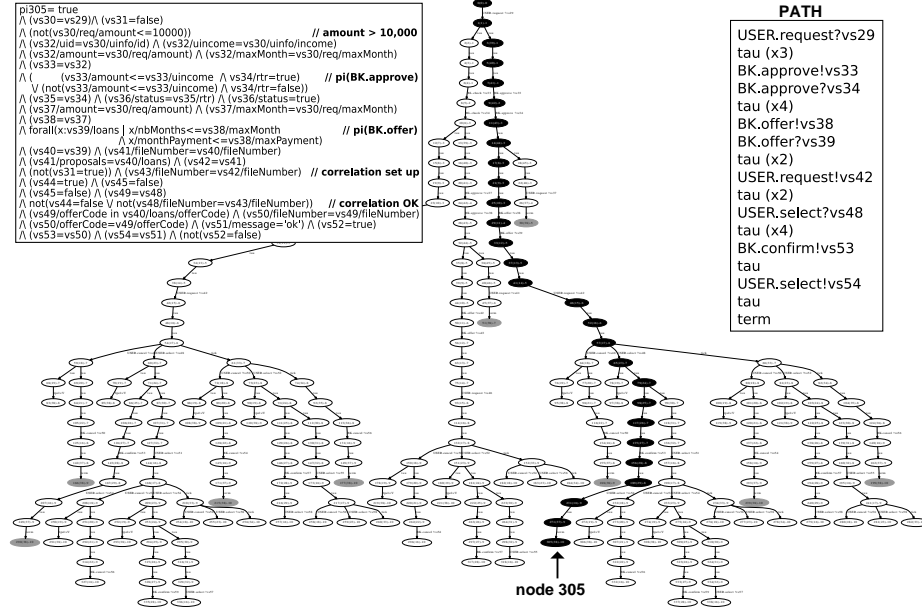

**Path length criterion.** STS may contain loops that would cause SET unboundness. To solve this issue out, we take into account a path length criterion while computing the SET. Given a constant  $k$ , we stop the SET computation at some node whenever this node is at  $k$  edges from the SET root. In order to take into account the fact that interactions are the most important part of orchestrations, only non- $\tau$  transitions can be counted. Let us note that in some cases this option could suffer from ( $\tau$ -)livelocks in the STS. Different cutting criteria have been proposed in the literature, *e.g.*, the inclusion criterion in [16], where the SET computation stops at one node when an equivalent node (in terms of program variable valuations validating the path constraint) is on the path to the SET root. Yet, this does not prevent the need to a path length criterion [16].

**Application.** The SET computed from the Figure 4 STS is presented in Figure 5. There are 10 leaves corresponding to termination (in gray). The zoom presents the path (in black) we use for demonstration in the next Section. Its final node is number 305, and its path condition,  $\pi_{305}$  is also given in the Figure.

## 5 Test Case Realisation and Testing Architecture

In this Section we present the way symbolic test cases are realised and executed on an orchestration implementation. The distinctive features of our approach can be summarised as follows:

- **Functional testing with a SET path coverage criterion.** For the time being, we support two criteria: all paths with length  $n \leq k$ , and all complete

Fig. 5. xLoan Example – Symbolic Execution Tree ( $k=10$ ,  $\tau_s$  not counted)

paths (a path ended with  $\checkmark$ ) with length  $n \leq k$ . Paths are constructed in a DFS way.

- **Symbolic input-output trace inclusion.** The conformance relation we use is trace inclusion extended to our symbolic context. It can be related to the conformance relation defined in [15, 16] that inspired our work (see *Related Work*). However, we do not require input-enabledness since, for Web services, an exception is returned whenever an unexpected event is received by the service.
- **Online realisation of symbolic test cases.** Test case realisation is performed step by step, by interacting with the Service Under Test (SUT). This is to avoid emitting erroneous verdicts. Take a path  $p?x.p!y$ , with  $\sigma = \{x \rightarrow v_{s_0}, y \rightarrow v_{s_1}\}$  and  $\pi = v_{s_0} > 2 \wedge v_{s_1} > v_{s_0}$ . Realisation all-at-once would yield a realised path  $p?v_{s_0}.p!v_{s_1}$  with, *e.g.*,  $\{v_{s_0} \rightarrow 3, v_{s_1} \rightarrow 4\}$ . Suppose now we send message  $p$  with value 3 to the SUT and that it replies with value 5. We would emit a *Fail* verdict ( $5 \neq 4$ ), while indeed 5 would be a correct reply ( $5 > 3$ ).
- **Branching awareness.** The SUT may send different outputs at some point in its execution due to non-determinism (*e.g.*, due to a **flow** activity in the implementation). Outputs are non-controllable events from the point of view of the tester. Therefore, a path is realised in the context of its SET (see Alg. 1).

**Algorithm 1:** Online Testing Algorithm

---

**Data:** SET + a distinguished path  $p$ ,  $path\ p = n_1l_1n_2l_2 \dots l_{k-1}n_k$  ;

```

begin
   $\pi = \pi_k; i := 1; rtr := Pass$  ;
  while  $i < k$  and  $rtr = Pass$  do
    switch  $l_i$  do
      case  $USER.e?x_s$ 
         $val := (SOLVE(\pi)[x_s]);$ 
        try {send ( $e(val)$ );  $\pi := \pi \wedge x_s = val$ ;}
        catch ( $e \in Ex$ ) {  $rtr := Fail$ ; }
      case  $USER.e!x_s$ 
        start TAC;
        try {receive ( $e(val)$ );  $\pi = \pi \wedge (x_s = val)$ ;
            if  $\neg SOLVE(\pi)$  then  $rtr := Fail$ ; }
        catch (timeout.TAC) {  $rtr := Fail$ ; }
        catch (receive  $e'$ ) { if  $e' \in may(\eta_i)$  then  $rtr := Inconclusive$ ;
            else  $rtr := Fail$ ; }
      case  $\chi$ 
        wait(1 unit of time);
      otherwise
        skip;
    end
     $i := i + 1$ ;
  end
  return  $rtr$ ;
end

```

---

**5.1 Online Testing Algorithm**

Online testing is presented in Algorithm 1. Its input is the SET with a distinguished symbolic path we want to test. The algorithm then animates the path by interacting, over messages for the **USER** partnerlink, with the SUT. Accordingly, input (resp. output) events in the path correspond to messages sent (resp. received) by the tester. Generation of data in sent messages and checking of data in received messages is supported using constraint solving over a Path Condition (PC). Initially PC corresponds to the path condition ( $\pi$ ) in the last node of the path we test. The treatment of the path edges is then as follows.

- **Input events.** The tester has to generate a message to be sent to the SUT. For this, PC is solved (always succeeds, or the edge would have been cut off in the SET computation). We use the instantiation of the event variable,  $x_s$ , to send the message, and to update the PC. If the sent message yields an exception, we return a *Fail* verdict, else we pass to the next edge.
- **Output events.** The treatment of output events corresponds to message reception in the tester. Whenever an emission by the SUT is foreseen, a timer, *TAC*, is set up. Then three cases may occur. (i). If the timer elapses, we return a *Fail* result. (ii). If we receive the expected message before this, we update the PC with this new information and try to solve it. If it succeeds

we continue to the next edge. If it fails we return a *Fail* verdict. If we do not get a result in a given amount of time we return an *Inconclusive* verdict (not in the Algorithm for simplicity). (iii). If we receive an unexpected event, we check in the SET if it is due to the specification non-determinism. If not, we return a *Fail* verdict. If it is the case, we return an *Inconclusive* verdict and the test path needs to be replayed in order to exhibit the behaviour that this test path characterises (for this we assume SUT fairness). Fault output events are supported in the same way

- **Time passing** ( $\chi$ ) corresponds to the passing of one unit of time. Accordingly, the tester waits for this time before going to the next event in the path. The unit of time is computed from the specification (one hour in our example). Other events are skipped (see below, *Discussion*, about an alternative for gray-box testing).

## 5.2 Tool Support and Application

In this part, we end the application to the xLoan example, focusing on the online testing algorithm and on tool support. Our approach is automated by means of prototypes written in Java (BPEL to STS) and in Python (STS to SET) that serve as a proof of concept. As far as constraint solving is concerned, we chose the UML2CSP tool [17], which supports OCL constraint solving over UML class diagrams, that correspond to the constraints we have on XML schema data. Additionally, UML2CSP is able to generate witness object diagrams when the constraints are satisfiable. More precisely, in order to reuse this tool, we proceed as follows:

- we translate XML schema definitions into an UML class diagram, see Figure 2. Additionally, domain limits are set up in UML2CSP according to uniformity hypotheses, *e.g.*, here we have set  $\text{maxMonth}:\{12,24,36\}$  and  $\text{maxPayment}:[1000..100000]$ . This step is done only once.
- to check if some  $\pi$  is satisfiable *before* sending a message, an additional root class (Root) is created wrt. the UML diagram, with as many attributes as symbolic variables in  $\pi$ . The  $\pi$  constraint is translated in OCL. If  $\pi$  is satisfiable, UML2CSP generates an object diagram. From it we get data for the variable of interest to be sent (step  $val := (\text{SOLVE}(\pi)[x_s])$  in Alg. 1).
- to check if some  $\pi$  is satisfiable *after* receiving a message, we perform as before, but adding an OCL constraint enforcing that the symbolic variable of the reception is equal to the data effectively received (steps  $\pi = \pi \wedge (x_s = val)$  and  $\neg \text{SOLVE}(\pi)$  in Alg. 1).
- cutting infeasible paths in the SET computation is a sub-case of satisfaction before message sending (the generated object diagram is discarded).
- strings are treated as integers which represent an index in an enumerated type. This corresponds to a set of specific string constants for the test.

For the time being, interaction with UML2CSP is manual. The automation of this step is under process as part of an Eclipse plug-in we are developing.

<pre> &lt;soapenv:Envelope xsi:..."http:... &gt; &lt;soapenv:Body&gt; &lt;ns2:RequestIn&gt;   &lt;ns3:uInfo&gt;     &lt;id&gt;1&lt;/id&gt;     &lt;name&gt;Simpson&lt;/name&gt;     &lt;income&gt;10002&lt;/income&gt;   &lt;/ns3:uInfo&gt;   &lt;ns3:req&gt;     &lt;amount&gt;10001&lt;/amount&gt;     &lt;maxMonth&gt;12&lt;/maxMonth&gt;     &lt;maxPayment&gt;1000&lt;/maxPayment&gt;   &lt;/ns3:req&gt; &lt;/ns2:RequestIn&gt; &lt;/soapenv:Body&gt; &lt;/soapenv:Envelope&gt; </pre>	<pre> &lt;soapenv:Envelope xsi:..."http:... &gt; &lt;soapenv:Body&gt; &lt;ns2:RequestOut&gt;   &lt;status&gt;true&lt;/status&gt;   &lt;fileNumber&gt;1&lt;/fileNumber&gt;   &lt;ns3:proposals&gt;     &lt;offerCode&gt;1&lt;/offerCode&gt;     &lt;nbMonths&gt;12&lt;/nbMonths&gt;     &lt;monthPayment&gt;918&lt;/monthPayment&gt;     &lt;ns3:rate&gt;       &lt;type&gt;fixed&lt;/type&gt;       &lt;value&gt;10&lt;/value&gt;     &lt;/ns3:rate&gt;   &lt;/ns3:proposals&gt; &lt;/ns2:RequestOut&gt; &lt;/soapenv:Body&gt; &lt;/soapenv:Envelope&gt; </pre>

Fig. 6. xLoan Example – a Sent and a Received Message (parts of)

Experiments have been applied on an implementation of xLoan which is not isomorphic to its specification as, *e.g.*, the BPEL code relies on additional boolean variables rather than on the workflow structure to decide if the subprocess for loan proposal selection or cancelling is applicable. The implementation size is 246 lines long (186 XML tags). In order to demonstrate our on-line algorithm, we take one of the 10 complete paths we have in the SET (see Fig. 5). Due to lack of room we focus on the first interaction steps of the path (loan request, loan reply). The first call to UML2CSP with the end path condition,  $\pi_{305}$ , enables one to retrieve values for the `RequestIn` message (id, name, income, amount, maxMonth, maxPayment), *e.g.*, the part of the path condition relative to the requested amount generates the `Context Root` `inv PC : not(self.vs30.req.amount<=10000)` OCL constraint, and value 10001 for the request amount. We then generate the message data in Figure 6, left, and send it using SOAPUI<sup>3</sup>. The corresponding received message is in Figure 6, right. We translate this data as an OCL constraint and solving it with UML2CSP we are able to show that it is a correct output. We may then proceed generating data for a correct offer selection (`offerCode=1`).

### 5.3 Discussion

We have experimented the application of our framework for functional testing based on structural criteria. We think that it could be used in other contexts. First, one may need to test –at design-time, or at run-time for dynamic service binding– if a SUT may serve as a sub-service, being given a specification of the way one would like to communicate with it. This could be achieved by generating a partner service description [18] for this specification, and then apply our technique. Besides, supporting test objectives described as a directed acyclic STS with leaves tagged using  $\{Pass, Fail\}$  could be performed using the STS product [19] of this STS with the specification STS prior to SET generation.

Additionally, one could have a gray-box point of view over orchestrations using the information available in the SET. We are experimenting another version

<sup>3</sup> <http://www.soapui.org/>

of Algorithm 1 where communications with the partners are no longer skipped by the tester which receives invocations of the SUT and replies as if it was the sub-service (generating data respecting the  $\pi$  boolean formula in the sub-service signature specification). For this, we use the same constraint satisfaction approach as presented before.

## 6 Related Work

The state of practice in service testing has been limited for a long time to the use of tools such as SOAPUI or BPELUnit [20] that release from the burden of the translation into SOAP messages, operation calling and test management. However, test-cases were mainly generated using empirical approaches, often without automation.

In the last years, the software testing community has started to get involved in the service field. As a consequence, several works have tried to bridge the gap between current practice in service testing and state-of-the-art formal and automated software testing. One way to address this issue is to focus on the service signatures, *i.e.*, their WSDL description [21]. This enables to test operations independently. However, WSDL provides neither a semantic information on services nor a behavioural description of them, which is important in presence of composite (orchestration) services.

To the contrary, we chose to focus on this complementary part of orchestrations. This point of view has been adopted by several works, through white-box testing. Approaches based on control-/data-flow coverage criteria are presented in [22–24]. Classical testing data-flow criteria are revisited in [22] in order to be suitable to services. A control-flow algorithm is combined in [23] with rewriting graphs to support XPath expressions. The use of BPEL model-checking for white-box test case generation has been proposed in [25, 26]. In both cases, test cases are considered as counter-examples and generated, according to several coverage criteria, with the SPIN model-checker. While [25] uses an intermediary model, [26] transforms directly BPEL into Promela. All these white-box approaches assume that the implementation source code is available.

In earlier work [10], we have addressed gray-box testing using translation of BPEL into the IF language and the extension of the IF simulator to generate tests according to a test objective. However, the use of data domain enumeration yields state explosion. To circumvent this problem, we propose in this paper a black-box testing approach using translation into STS and symbolic execution. We took inspiration from previous work on symbolic testing [19, 16, 15, 27]. The works in [19, 16], still, did not address components or services. Application to this domain has first been proposed in [15], and later in [27], from a theoretical and generic point a view, without a specification/implementation language in mind. In our work, we propose a comprehensive language-to-language approach with BPEL as target language. Accordingly, compared to the above-mentioned works, we take into account BPEL specific features in test-case derivation.

## 7 Conclusion and Perspectives

With the development of service reuse through their aggregation in added-value composite services, the testing of orchestrations has become a topical issue. In this paper we have presented a framework for orchestration testing based on symbolic transition systems which, compared to related work, supports the rich XML-based data types used in (Web) services without suffering from state explosion issues. This framework also proposes a comprehensive language-to-language approach, as it deals with both the retrieval of formal models from real service specification languages and with the execution of test cases using the SOAPUI API. Although we tackle BPEL to STS transformation, we advocate that transformations rules can be defined from other languages with workflow features (UML, BPMN) and accordingly provide the software architect with a richer specification environment.

Ongoing work is relative to the re-engineering of our tool prototypes and their integration in a plug-in extension of the Eclipse BPEL Designer, following [28]. A first perspective of our work is to support conformance testing based on test objectives. This would provide a valuable alternative to the path length criterion when dealing with infinite SET. Another perspective is relative to the supported basic XML types, currently only integers and strings. Using String databases, as proposed in [21], in place of simple enumerated values would enhance the tests relevance. Finally, supporting additional parts of BPEL, including compensation/termination handlers and string operators would enable to target a wider range of BPEL specifications.
